1. Executive Summary

The purpose of this study was to develop comprehensive statewide controlled and uncontrolled emissions inventories for drilling rig engines associated with onshore oil and gas exploration activities occurring in Texas. Oil and gas exploration and production facilities are considered some of the largest sources of area source emissions in certain geographical areas, dictating the need for continuing studies and surveys to more accurately depict these activities. The current inventory effort builds off of the previous 2009 study prepared for the TCEQ, 2009 Drilling Rig Emission Inventory for the State of Texas (July 15, 2009, prepared by ERG), which focused exclusively on drilling activities. The previous effort is expanded upon by improving the activity data (well counts, types, and depths) used to estimate emissions, and uses the drilling rig engine emission profiles developed in the 2009 study. The improved well activity data was obtained through acquisition of the "Drilling Permit Master and Trailer" database from the Texas Railroad Commission (TRC). The activity data and emissions characterization data were then used to develop controlled and uncontrolled drilling rig engine emissions inventories for the years 1990, 1993, 1996, and 1999 through 2040.

The rig profiles developed in the 2009 study provided:

- The average number of engines on a rig
- Average engine model year and size (hp)
- Average load for each engine
- Engine function (draw works, mud pumps, power)
- Average engine hour data for each well (total hours)
- Average well drilling time (actual number of drilling days)
- Average well completion time (number of days needed for well completion activities)
- Average well depth

Target pollutants for this study include nitrogen oxides (NO_x), volatile organic compounds (VOC), carbon monoxide (CO), particulate matter (PM_{10} and $PM_{2.5}$), sulfur dioxide (SO_2), and hazardous air pollutants (HAP). Emissions were calculated for each county in Texas where drilling occurred and are provided in annual tons per year and by typical ozone season day. Emission estimates for years prior to 2011 were based on TRC records of oil and gas well completions during those years, and U.S Department of Energy (DOE), Energy Information Administration (EIA) oil and gas production growth estimates were used to develop the projections for the years 2011 forward.

Emissions estimates developed from this inventory project may be used for improved input data to photochemical air quality dispersion modeling, emissions sensitivity analyses, State Implementation Plan (SIP) development, and other agency activities.

The final inventory estimates are provided in Consolidated Emissions Reporting System (CERS) Extensible Markup Language (XML) to facilitate entry of the data into the state's TexAER (Texas Air Emissions Repository) database, and for the purposes of submittal to US EPA. For purposes of XML preparation, Source Classification Code (SCC) 23-10-000-220 (Industrial Processes - Oil and Gas Exploration and Production - All Processes - Drill Rigs) was used, consistent with the 2009 study.

Table 1-1 summarizes the statewide annual emission estimates for 1990, 1993, 1996, and 1999 through 2040. Figures 1-1 through 1-3 present this same information in chart form. Note that the PM_{10} and $PM_{2.5}$ values are so close together that they are difficult to distinguish in Figure 1-3. Appendix A provides the corresponding statewide emissions estimates for HAPs.

Table 1-1. Statewide Drilling Rig Estimates (Tons/Year)

Year	CO	NO_X	$PM_{2.5}$	PM_{10}	SO_2	VOC
1990	13,366	25,308	2,457	2,533	3,037	3,462
1993	15,193	29,354	2,743	2,828	3,141	3,940
1996	15,502	33,037	2,737	2,822	4,093	4,044
1999	10,568	24,159	1,707	1,760	1,647	2,769
2000	14,570	33,578	2,350	2,422	2,290	3,798
2001	16,910	38,960	2,726	2,810	2,641	4,410
2002	11,027	27,974	1,919	1,978	2,100	2,955
2003	14,234	37,220	2,471	2,548	2,825	3,803
2004	15,057	40,164	2,607	2,688	3,040	4,047
2005	17,706	47,798	3,068	3,163	3,606	4,788
2006	15,235	52,497	2,463	2,539	4,290	4,135
2007	16,071	57,197	2,320	2,392	909	4,443
2008	17,745	59,261	2,615	2,696	1,033	4,593
2009	8,464	29,231	1,244	1,282	523	2,202
2010	7,182	24,531	1,024	1,056	21	1,846
2011	6,869	23,254	1,016	1,047	21	1,725
2012	6,949	22,920	1,028	1,060	22	1,716
2013	5,893	19,878	652	672	19	1,687

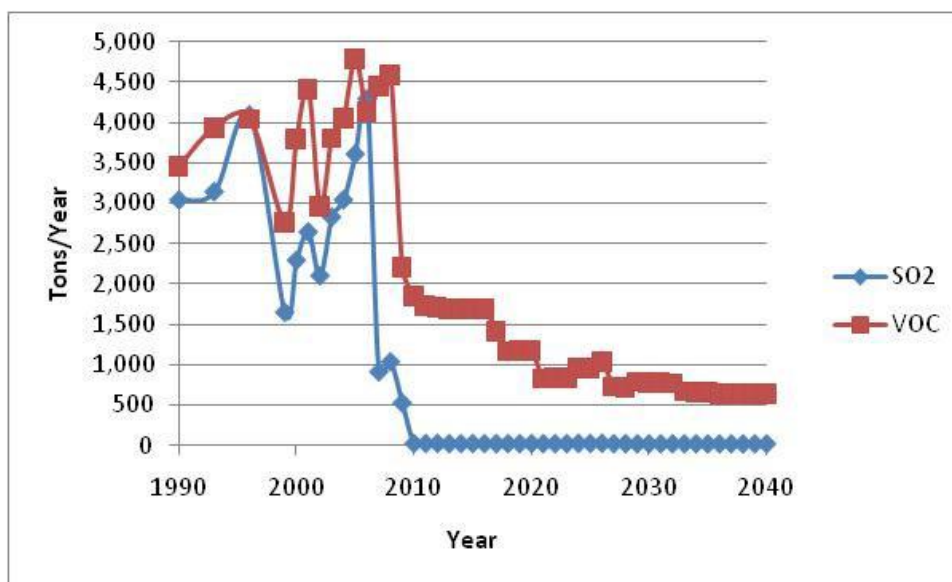

Figure 1-3. Statewide Drilling Rig Estimates (PM$_{10}$ and PM$_{2.5}$ Tons/Year)
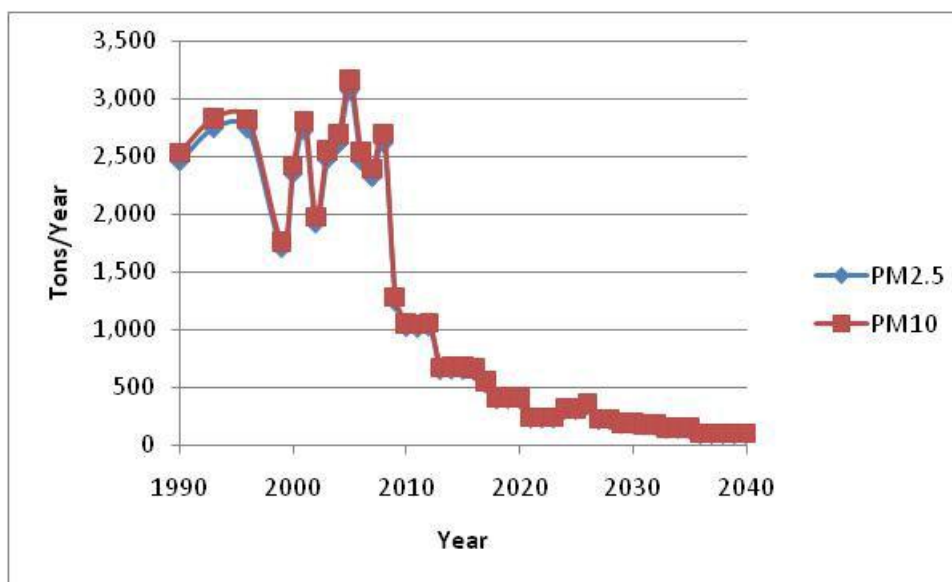

The study results provide a significant improvement upon the 2009 effort, utilizing improved gap filling methods for the TRC dataset to obtain a more complete and accurate set of drill rig activity. In addition, this study utilized historical drilling data from the TRC to estimate past emissions, rather than relying on surrogate based back-casting from a base year, as was done in the previous study. Finally, the study greatly expanded the time horizon of the previous study, ranging from 1990 with projections through 2040. The result is a reliable, temporally resolved profile of county-level drilling activity emissions. The successful update of the state's TexAER database system

with this data, associated with a new area source SCC, will allow for improved SIP and trend analysis for all regions of the state.

Based on the projected oil and gas production levels in Texas from the EIA, drilling activity is estimated to remain relatively constant across the state from 2011 through 2035. However, the continued phase-in of more stringent Non-Road diesel engine emission standards should cause a steady decrease in drilling-related emissions over time. SO_2 emissions levels in particular are estimated to have fallen precipitously due to the introduction of the ultra-low sulfur standards for diesel fuel in 2010, and should remain extremely low for the foreseeable future.

An analysis of county-level data found that the vast majority of Texas counties produced some level of emissions associated with drilling activities (206 of 254 counties) in the 2010 base year. However, the county-level distribution of NO_x emissions is highly skewed, with 14 counties being responsible for 50 percent of total statewide NO_x in 2010. In addition, the preponderance of the high NO_x emitting counties were predominantly in West and North-Central Texas.

While the emissions inventory results provide an excellent basis for assessing historical emissions levels, significant sources of uncertainty remain. Most importantly, projections of future activity are highly uncertain, subject to significant rises and falls depending upon economic factors and associated oil and gas prices. Accordingly, periodic refinement of the activity data used for projected years 2011 through 2040 is strongly recommended to account for such factors. In addition, the contribution of hydraulic fracturing operations to drilling activity emissions remains unknown at this time.

2.   Introduction

The purpose of this study was to develop comprehensive statewide controlled and uncontrolled emissions inventories for drilling rig engines associated with onshore oil and gas exploration activities occurring in Texas. Oil and gas exploration and production facilities are considered some of the largest sources of area source emissions in certain geographical areas, dictating the need for continuing studies and surveys to more accurately depict these activities. The current inventory effort builds off of the previous 2009 study prepared for the TCEQ, 2009 Drilling Rig Emission Inventory for the State of Texas (July 15, 2009, prepared by ERG), which focused exclusively on drilling activities. The previous effort is expanded upon by improving the activity data (well counts, types, and depths) used to estimate emissions, and uses the drilling rig engine emission profiles developed in the 2009 study. The improved well activity data was obtained through acquisition of the "Drilling Permit Master and Trailer" database from the Texas Railroad Commission (TRC). The activity data and emissions characterization data were then used to develop controlled and uncontrolled drilling rig engine emissions inventories for the years 1990, 1993, 1996, and 1999 through 2040.

While drilling activities are generally short-term in duration, typically covering a few weeks to a few months, the associated diesel engines are usually very large, from several hundred to over a thousand horsepower (hp). As such, drilling activities can generate substantial amounts of NO_x emissions. While previous studies have focused more intently on quantifying the ongoing fugitive VOC emissions associated with oil and gas production, significant uncertainty remains regarding the shorter term NO_x emission levels associated with drilling activity.

The activity and drilling rig engine emissions profiles developed under the 2009 study were used to develop emissions estimates of VOC, NO_x, CO, PM_{10} and $PM_{2.5}$, SO_2, and HAP for drilling rig engines across the state. Emissions are calculated on a county-level basis and provided in annual tons per year and by typical ozone season day.

Section 3.0 of this report provides an overview of the drilling process and identifies the types of activities and equipment that are commonly associated with drilling activity. Section 4.0 describes the development of the emissions inventory including how the activity data was compiled, how the model drilling rig emission profiles were developed, and how these model drilling rig emission profiles were combined with the activity data to develop the emission inventories, along with quality assurance measures applied. Section 5.0 summarizes the conclusions for this study and offers recommendations for future studies.

3. Drilling Rig Overview

3.1 Drilling Permits

All exploratory oil and gas drilling in Texas requires a permit. These permits are processed and maintained through the TRC. The drilling permits are available for review through the TRC website, and include well-specific data such as approval date, location (county), well profile (vertical, horizontal, directional), well depth, start or "spud-in" date, and well completion date. ERG obtained this data in electronic format through acquisition of the "Drilling Permit Master and Trailer" database. This database formed the basis of the activity data used to develop the historical emissions inventories (those prior to 2011).

3.2 Drilling Rig Overview

Air pollutant emissions from oil and gas drilling operations originate from the combustion of diesel fuel in the drilling rig engines. The main functions of the engines on an oil and gas drilling rig are to provide power for hoisting pipe, circulating drilling fluid, and rotating the drill pipe. Of these operations, hoisting and drilling fluid circulation require the most power.

There are two common types of rigs currently in use – mechanical and electrical. In general, mechanical rigs have three independent sets of engines. The first set of engines (draw works engines) are used to provide power to the hoisting and rotating equipment, a second set of engines (mud pump engines) are dedicated to circulating the drilling fluid which is commonly referred to as "mud", and a third set of engines (generator engines) are used to provide power to auxiliary equipment found on the drill site such as lighting equipment and heating and air conditioning for crew quarters and office space. There may be one, two, or more draw works engines, depending on the input power required. There are typically two mud pumps for land rigs, with each mud pump independently powered by a separate engine. The mud pump engines are typically the largest engines used on a mechanical rig. Finally, there are typically two electric generator engines per mechanical rig, with one running continuously and the second serving as a stand by unit.

Electrical rigs are typically comprised of two to three large, identical diesel-fired engine-generator sets that provide electricity to a control house called a silicon controlled rectifier (SCR) house. Electricity from the SCR house is then used to provide power to separate motors on the rig. In this configuration, there are dedicated electric motors used for the draw works/hoisting operations, the mud pumps, and other ancillary power needs (such as lighting). The generator engines are loaded as required to meet fluctuating power demands, with one unit typically designated for standby capacity. The

trend in new rig design is almost exclusively towards electric rigs, except perhaps for the smallest rigs. This is probably due to the relative expense of engines versus motors, both in terms of initial cost and maintenance. Today, electrical rigs are common, especially for larger rigs (Bommer, 2008).

After drilling and casing a well, it must be "completed." Completion is the process in which the well is enabled to produce oil or gas. Once the desired well depth is reached, the geological formation must be tested and evaluated to determine whether the well will be completed for production, or plugged and abandoned. To complete the well production, casing is installed and cemented and the main drilling rig is dismantled and moved to the next site. A smaller rig, called a completion rig (also known as a workover rig), is then moved on site to bring the well into production, to perforate the production casing and run production tubing to complete the well. Typically, the completion rig is a carrier-mounted arrangement and may be on-site for several days to a week or more depending on well depth and other factors. The completion rigs hoist smaller loads and pump at lower rates than the drilling rigs, and therefore require much smaller engine capacity.

Increasingly, reservoir productivity is enhanced by the application of a stimulation technique called hydraulic fracturing.[1] Fracturing jobs are often high rate, high volume, and high pressure pumping operations. They are accomplished by bringing very large truck- mounted diesel-powered pumps (e.g., 2,000 hp or more) to the well site to inject the fracturing fluids and material, and to power the support equipment such as fluid blenders. In this process, the reservoir rock is hydraulically overloaded to the point of rock fracture. The fracture is induced to propagate away from the well bore by pumping hydraulic fracturing fluid into the well bore under high pressure. The fracture is kept open after the end of the job by the introduction of a solid proppant (sand, ceramic, bauxite, or other material), by eroding the sides of the fracture walls and creating rubble by high injection rates, or for carbonate formations, by etching the walls with acid. The fracture thus created and held open by the proppant materials becomes a high conductivity pathway to the well bore for reservoir fluid.

Fracturing generally takes place directly after removal of the completion rig in order to initiate gas production. Therefore it is reasonable to assume that most fracturing occurs within days or weeks of well completion. The frequency and timing of both fracturing as well as re-fracturing (wherein a well nearing exhaustion is fractured again in order to re-invigorate gas flow), is not contained in the TRC database and is unknown.

Oil and gas wells are commonly classified as vertical, directional, or horizontal wells, depending on the direction of the well bore. Vertical wells are the most common, and

---

[1] Hydraulic methods are the only type of fracturing known to occur with any frequency in the shale formations in Texas.

are wells that are drilled straight down from the location of the drill rig on the surface. Directional wells are wells where the well bore has not been drilled straight down, but has been made to deviate from the vertical. Directional wells are drilled through the use of special tools or techniques to ensure that the well bore path hits a particular subsurface target, typically located away from (as opposed to directly under) the surface location of the well. Horizontal wells are a subset of directional wells in that they are not drilled straight down, but are distinguished from directional wells in that they typically have well bores that deviate from vertical by 80 - 90 degrees. Horizontal wells are commonly drilled in shale formations. Once the desired depth has been reached (the well bore has penetrated the target formation), lateral legs are drilled to provide a greater length of well bore in the reservoir.

In vertical wells, a single fracture job per reservoir is commonly done. In high angle or horizontal wells, it is common to perform multiple fracturing jobs (multi stage fracturing) along the path of the bore hole through a reservoir. The measure of the power required is based on the hydraulic horsepower necessary to fracture the well. Although very short in duration (typically less than a day), fracturing activities may result in substantial NO_x emissions due to the very high horsepower requirements.

4. Emissions Inventory Development and Results

The activity data from the TRC and the model rig emissions profiles developed in the 2009 study for each model rig well type category were utilized to develop emissions estimates for selected target years, as described in the following sections. The 2009 study, which serves as the basis for the current inventory development, attempted to characterize activity and emissions for all significant sources associated with drilling activities. Note that small engines – e.g., 25 hp and less – were excluded from the survey effort due to their anticipated low levels of emissions. In addition, the survey results did not find any engines powered by gasoline or natural gas, so emission inventory estimates were limited to diesel engines.

EPA's NONROAD emission factor model estimates emissions for "Other Oil Field Equipment" which includes fracturing rigs, mechanical drilling engines, oil field pumps, pump jacks, and seismograph rigs (PSR 1998). Of these subcategories, only the first three are involved in drilling activities. The 2009 survey results successfully profiled activity and population levels for drilling engines and pumps, as well as electrical generators used to power auxiliary equipment as described in the previous section.

During the data collection phase of the 2009 study, information was also solicited from respondents regarding fracturing activities. As part of their survey response, drilling contractors and oil and gas exploration companies occasionally provided some qualitative or quantitative information regarding fracturing, but the responses were highly variable in content and format. In general, the indication was that fracturing was a short-term activity (less than one day in duration), and that pump trucks containing multiple, large diesel-fired engines could be used simultaneously to pump the fracturing fluids into the well.[2]

Specific information regarding the frequency of fracturing events and the total hp-hours required per event were not generalizable to the inventory as a whole, however. Further investigation regarding fracturing was made by contacting service companies that provide fracturing services, as well as interviewing personnel at the TRC and researching the availability of fracturing data on-line through the TRC website. Two of the three service companies contacted provided some data for the fracturing activities performed in 2008, which varied from the use of five 1,250 hp pump engines for a total duration of 1 hour, to the use of seven 2,500 hp pump engines for a total duration of 12 hours. The third service company contacted did not provide any data.

---

[2] Note that these pump engines are different than the pumps used to circulate drilling fluid, as profiled for this inventory.

Unlike the drilling permit records obtained through the "Drilling Permit Master and Trailer" database, fracturing data is not compiled by the TRC or otherwise made readily available in any summarized format through any on-line queries or electronic datasets. However, images of individual well completion records (referred to as G-1 forms for gas well completions and W-2 forms for oil well completions) are available on-line through the TRC website. Using American Petroleum Institute (API) numbers from the TRC data, a random on-line search was performed to review the G-1 and W-2 records for approximately 1,200 wells. The G-1 and W-2 forms were only found for approximately one-third of these wells. These forms are frequently completed by hand, with inconsistent data being reported by individual well operators, with much of the data being incomplete. However, based on a review of the records we were able to identify, it appears that approximately 80% of the wells in the sample had some kind of fracturing activity occurring prior to well completion. (Given the short duration of fracturing activities, it is reasonable to assume that most or all of the emissions associated with fracturing occur in the same year as the emissions associated with drilling.) While data is not currently available under this project to provide emission estimates for fracturing activities, due to the large engine sizes used by the pump trucks, this is a source category that may be considered for inclusion in future emission inventory development projects.

4.1   Activity Data

4.1.1 Historical Activity

The Texas Railroad Commission (TRC) maintains oil and natural gas drilling permits for the state of Texas. ERG obtained a copy of the database in ASCII, position-delimited format from a TRC download on May 12, 2011. Using the TRC manual, ERG uploaded the database file into Microsoft Access. The database file contained over 650,000 unique drilling permit and well ID records from 1948 to mid-2011. ERG was tasked with identifying historical drilling activities which occurred in base years 1990, 1993, 1996, and from 1999-2010 for a total of 15 years. [3] In addition to descriptive information about each permit record (i.e., permit number, American Petroleum Institute (API) number, Well ID, etc.), the TRC data file contains information for when drilling began (Spud Date), when drilling was completed (Drilling Completion Date), wellbore profile type (vertical or horizontal), and permitted well depth.

It is important to note that approximately 19% of the data records did not contain both Spud Date and Completion Date, thus it could not be determined definitively if activity occurred during a base year of interest. It is believed that these records were administrative records, and no drilling activity was associated with these entries. Additionally, over 51% of the data records had either a Spud Date in 2011, finished

---

[3] Note that unlike the 2009 study, which back-cast well activity levels using surrogates, this study used actual historical activity levels for all years between 1990 and 2010.

drilling prior to 1990, or the entire drilling activity took place in a non-base year of interest (1991, 1992, 1994, 1995, 1997, or 1998). As such, these records were not included in the analysis. Finally, we identified approximately 4% of the data as having either a Spud Date or a Drilling Completion Date, but not both. We "flagged" these records as possibly occurring during a base year of interest. As a result, over 168,000 data records (~ 26%) were initially identified as having drilling activities occurring during one of the 15 years of interest.

Prior to calculating the activity data needed to calculate estimated drilling emissions, ERG reviewed the flagged records to potentially add to the records of interest. We used the TRC website (www.rrc.state.tx.us) to approximate surrogate Spud or Drilling Completion Dates. Specifically, if a Spud Date was missing, ERG used the TRC Permit Approved Date as a surrogate for Spud Date and Surface Casing Date or Well Completion Date as a surrogate Drilling Completion Date. However, since there were over 25,000 flagged records, it was not feasible to examine each one due to time and resource constraints. Therefore, we prioritized the flagged records by reviewing the deepest permitted wells first. As a result, we were able to identify nearly 15,000 more data records in which drilling occurred in a base year of interest.

Additionally, we verified base year data records in which the Spud Dates, Completed Drilling Dates, or permitted well depths were obvious errors. For example, permit ID = 618176 had a permitted well depth of 89,000 feet. In reviewing the TRC website, it was determined that the permitted well depth should have been 8,900 feet. Additional errors include Spud or Completed Drilling Dates that occurred prior to 1948 or after 2011. Also, it appears as if some years were transposed (e.g., 1990 vs. 1909) and these were corrected accordingly.

In some cases, drilling which occurred over multiple years was pro-rated for the base year of interest. In these situations, ERG calculated an "Average Drilling Rate" by dividing the permitted well depth by the number of drilling days, which is the number of days between the Completed Drilling Date and the Spud Date. The "Average Drilling Rate" was then used to pro-rate the total drilling days to each year. For example, permit ID = 486390 had a Spud Date of December 29, 2000, a Drilling Completion Date of January 8, 2001, and a total permitted well depth of 4,500 feet. Based on the Spud Date and Drilling End Date, it is assumed that drilling was continuous for 11 days. Therefore the "Average Drilling Rate" for this well was assumed to be 409.1 ft per day, and the 2000 pro-rated drilling was set to 1,227 feet for 2000 and 3,273 feet for 2001 (4,500 ft/11 days = 409.1 ft per day; 409.1 ft per day * 8 days = 3,272.8 ft; 409.1 ft per day * 3 days = 1,227.3 feet).

In total, ERG identified over 183,000 TRC permit records with drilling activity assigned to the target years. Each data record was also classified by three different wellbore

profile types defined during the 2009 study: "vertical well ≤ 7,000 feet"; "vertical well > 7,000 feet"; and "horizontal/directional well". These well type categories were selected to characterize three broadly different rig operation and engine type profiles, as discussed in detail in the 2009 report. The total amount of feet drilled was then summed to the county-level by wellbore profile type for each year.

ERG's processed drilling activity records covered the vast majority of TRC drilling records for the target years: of the 188,533 total wells drilled during the target years between 1990 and 2010 (as per the TRC database), ERG successfully characterized and processed 183,211 wells, or 97.2% of all recorded activity. The remaining wells could not be characterized adequately due to irresolvable data gaps or similar data inconsistencies.

4.1.2 Projected Activity

2011 through 2040 projected activity data were developed using 2010 as the base year activity data from the TRC and forecasting future activity based on US DOE Energy Information Administration (EIA) projections of oil and gas production for the Midcontinent, Southwest and Gulf Coast regions from the Annual Energy Outlook 2011, Reference Case.   The EIA data tables (specifically Supplemental Tables 132 and 133) present estimated crude oil and natural gas production estimates for the years 2008-2035. The geographic level of the projected data is by EIA Region.

Portions of Texas fall into three EIA Regions: Gulf Coast (Region 2); Southwest (Region 4); and Midcontinent (Region 3). The majority of the State is in the Gulf Coast and Southwest EIA Regions. Only a small portion (area to the west of Oklahoma) is in the Midcontinent Region. Figure 4-1 shows the EIA regions and their coverage in Texas.

Using the above figures, ERG developed a direct correspondence between EIA regions and TRC regions, as follows:

- EIA Midcontinent => TRC District 10
- EIA Southwest => TRC Districts 7b, 7c, 8, 8a, 9
- EIA Gulf Coast => TRC Districts 1 - 6

Using these assignments ERG developed growth projections through 2035 for the three different county groupings - see Appendix B for county groups.

Table 4-1 and Table 4-2 show projected crude oil and natural gas production for the three relevant EIA Regions, from 2010 through 2035. The total percentage change for each year from 2011 through 2035 is presented relative to the base year of 2010.

This data was then used to calculate a projected growth factor (%) for each year from 2011 through 2035 for each county grouping by weighting the oil and gas percentage growth figures relative to the number of oil and gas wells completed statewide in 2010. (Growth rates for 2036 – 2040 are assumed to equal the 2035 rate). For example, the projected growth factor for 2011 for the EIA Gulf Coast (GC) region is calculated as follows:

2011 GC factor = ((% change from 2010 to 2011 in GC Crude Oil Production x number of oil well completions in 2010) + (% change from 2010 to 2011 in GC Natural Gas Production x number of gas well completions in 2010)) / (total number of oil and gas well completions in 2010)

Using the data in Table 4-1 and Table 4-2, combined with the statewide well completion counts, the projected growth factor for the EIA GC region in 2011 is:

2011 GC factor = ((9.8% x 5,392) + (-1.3% x 4,071)) / (5,392+ 4,071) = 5.0%

Table 4-3 shows the growth factors that were developed for each projected county grouping and year combination as a result of this analysis. These factors were then applied to the 2010 base year well depth totals by county to determine activity data for 2011 through 2035. These projections are based on the best data currently available, but should be revisited periodically given the volatile economic nature of oil and gas prices.

Appendix C contains a summary of the total well depth by county and year for each model rig well type category.

4.2 Model Rig Emission Profiles

4.2.1 Model Rig Engine Profiles

The 2009 study established rig engine profiles for three distinct model rig categories for the following well types and depths based on the results of the data collection survey:

- Vertical wells less than or equal to 7,000 feet;
- Vertical wells greater than 7,000 feet; and
- Horizontal/Directional wells.

For each of these rig categories, a model rig engine profile was developed. In order for the model rig engine profile data to be applied consistently to the TRC activity data, the survey results were normalized to a 1,000 foot drilling depth. This was accomplished by dividing the total drilling hours for each engine included in each survey by the well depth for that survey to obtain the hours of operation per engine per 1,000 feet of drilling depth.

As the engine profiles and functions for engines used on mechanical rigs and electrical rigs are distinctly different, separate engine profiles for mechanical and electrical rigs were developed for each model rig well type category.

The following average engine parameters were calculated for each model rig well type category using a weighted average for each parameter based on the number of wells associated with each survey:

- Number of engines by rig type (i.e., mechanical draw works, mud pumps, and generators; electrical rig engines; and completion engines)
- Engine age
- Engine size (hp)
- Engine on-time (hours/1,000 feet drilled)
- Overall average load (%)

The weighted averaged engine parameters developed for each model rig category by rig type in the 2009 study are summarized in Table 4-4.

Table 4-4. Model Rig Engine Parameters

Model Rig Category	Rig Type	Engine Type	# of Engines	Average Age (yrs)	Engine Size (hp)	Hours/1,000 ft drilled	Average Load (%)
Vertical <= 7,000 ft	Mechanical	Draw Works	1.60	7	442	30.8	51.8
		Mud Pumps	1.69	6	428	29.4	45.9
		Generator	0.97	4	330	28.3	70.4
Vertical > 7,000 ft	Mechanical	Draw Works	2.01	25	455	35.9	47.4
		Mud Pumps	1.62	18	761	33.2	46.0
		Generator	2.00	10	407	19.3	78.7
	Electrical		2.15	2	1,381	62.6	48.5
Horizontal/ Directional	Mechanical	Draw Works	2.00	15	483	50.1	41.1
		Mud Pumps	2.00	6	1,075	36.4	42.6
		Generator	2.00	10	390	26.8	69.0
	Electrical		2.03	2	1,346	47.3	52.5
All	All	Completion	1.00	Default	350	10.0	43.0

As can be seen in Table 4-4, the expected trend toward larger engine sizes and more hours required per 1,000 feet for the deeper vertical wells and the horizontal/directional wells was verified. The older engine ages for the mechanical rigs used on the deeper vertical wells and the horizontal/directional wells are based on several surveys received for these well types that covered a large number of wells drilled by rigs with older engines. However, as noted in the 2009 study report, the future trend for these types of wells is towards the use of electrical rigs, and the average age of the engines used on the electrical rigs for these well types is only two years.

4.2.2 Model Rig Emission Factors

Using the model rig engine parameters presented in Table 4-4, EPA's NONROAD2008a model was modified to develop criteria pollutant emission factors for each model rig well type category for each year of the inventory (1990, 1993, 1996, and 1999 through 2040). Use of the NONROAD model allowed for expected reductions in emissions over time due to the phasing in of EPA's emissions standards for Non-Road diesel engines. [5]

Following the same methodology used in the 2009 emission inventory study, ERG modified the ACTIVITY.DAT file within NONROAD to reflect the appropriate hours per year and load factors for the required engine types (mechanical and electrical engines for each of the three rig types). Modifications were made for SCC 2270010010 (Diesel Other Oil Field Equipment). ERG also modified the TX.POP file to reflect the appropriate average hp for the engine type in question, and set the equipment population count to 1 in order to ease post-processing calculations. In addition, default NONROAD OPT files (input files containing basic model run information) were modified to reflect the statewide diesel fuel sulfur levels (see below) for each scenario year of interest. Accordingly, sets of OPT, activity, and population files were developed to model each well type/engine type/scenario year combination for this analysis.

Hazardous air pollutant (HAP) emission factors were developed by speciating the NONROAD emission factors based on HAP emissions profiles obtained from the California Air Resource Board's Speciation Profile Database (ARB, 2001). The specific speciation profiles used were Profile #818 for TOG and Profile #425 for PM. This methodology is consistent with the prior 2009 emission inventory study approach, as well as the speciation method used within the TCEQ's TexN emissions model. The HAP speciation factors used are presented in Table 4-5 and Table 4-6.

---

[5] While the NONROAD model was used to calculate drilling activity emissions (in order to more accurately capture emission standard phase in impacts), these emissions are actually classified as area sources emissions and reported as such to the TCEQ.

Table 4-5. PM$_{10}$ Speciation Factors

HAP	HAP CAS #	Weight Fraction of PM$_{10}$
Antimony	7440360	0.000036
Arsenic	7440382	0.000005
Cadmium	7440439	0.000040
Cobalt	7440484	0.000011
Chlorine	7782505	0.000344
Lead	7439921	0.000042
Manganese	7439965	0.000040
Nickel	7440020	0.000019
Mercury	7439976	0.000030

Benzene	71432	0.02
Cumene	98828	2E-04
Ethylbenzene	100414	0.003
Formaldehyde	50000	0.147
Methanol	67561	3E-04
m-xylene	108383	0.006
Naphthalene	91203	9E-04
n-hexane	110543	0.002
o-xylene	95476	0.003
Propionaldehyde	123386	0.01
p-xylene	106423	0.001
Styrene	100425	6E-04
Toluene	108883	0.015

SO$_2$ emissions were based on fuel sulfur content profiles for Texas obtained from historical fuel sampling data performed for the TCEQ. The average diesel sulfur content (% weight) for a particular analysis year was developed using the county-level fuel parameter data contained in TCEQ's TexN model, weighted by the number of wells in each county in 2008. The statewide average diesel sulfur content values calculated are presented in Table 4-7 reflecting the reduced sulfur requirements over time.

Table 4-7. Annual Weighted Average Diesel Fuel Sulfur

Year	Sulfur (% weight)
1990	0.3015
1993	0.2693
1996	0.3138
1999	0.1733
2000	0.1717
2001	0.1708
2002	0.1706
2003	0.1700
2004	0.1692
2005	0.1678
2006	0.1665
2007	0.0320
2008	0.0317
2009	0.0321
2010+	0.0015

Mass emissions per 1,000 feet of drilling for each engine type were derived from NONROAD outputs. The activity levels entered into NONROAD corresponded to the hours required to drill 1,000 feet, so NONROAD outputs were uniformly normalized to these units. Total emissions for each engine type/drill rig category combination were calculated by dividing the NONROAD output emissions total by the fractional engine population for the appropriate engine model year (from NONROAD's by-model-year output), and then multiplying by the average number of engines for each drill rig type. For example, the average age for a shallow well mechanical draw works engine is 7 years. Therefore for a 1990 calendar year run, emissions for a 1983 engine are first identified in the NONROAD by-model-year output. Since the NONROAD population file was set to equal one unit (corresponding to all model years), NONROAD calculates the "population" of 7 year old engines to be 0.0386 (i.e., 3.86% of all engines operating in 1990). In order to calculate total emissions per 1,000 feet of drilling activity for this engine, the mass emissions associated with this model year are first divided by this population to obtain the mass emissions rate per year for one engine (e.g., 0.0015 tons per year CO per 0.0386 engines = 0.039 tons per year per unit). Finally, this values is multiplied by the average number of engines of this type for the given well type (e.g., 1.6 mechanical draw works engines per shallow well drill rig) to obtain the emission factor expressed as mass emissions for each engine category/well type combination per 1,000 feet of drilling activity.

Total hydrocarbon (THC) exhaust emissions from the NONROAD model were converted to VOC and TOG using ratios of 1.053 and 1.070, respectively (U.S. EPA, 2005a). Crankcase THC emissions were assumed to be equivalent to both VOC and TOG (U.S.

EPA, 2005b). For diesel Non-Road engines, PM_{10} is assumed to be equivalent to PM, while the $PM_{2.5}$ fraction of PM_{10} is estimated to be 0.97 (U.S. EPA, 2005a).

Table 4-8, Table 4-9, and Table 4-10 contain the criteria pollutant emission factors developed for each model rig well type category for the emission inventory target years. Note that emission factors for uncontrolled emission inventory estimates were set equal to the 1990 factors below, as these pre-date the introduction of diesel engine controls.

Table 4-8. Emission Factors for Vertical Wells <= 7,000 feet (tons/1,000 feet)

4.3   Emission Estimation Methodology

Once the total depth drilled per year was aggregated by model rig well type category, and the emission factor profile for each model rig well type category was developed, county level emissions for each model rig well type category were estimated by multiplying the total depth drilled by county by the emission factors developed through use of the 2009 study survey data and the NONROAD model, as follows:

$$E_{poll}/type = (Depth\ (1{,}000\ feet/yr)) \times (EF_{poll}\ (tons/1{,}000\ feet))$$

Where:

$E_{poll}/type$ = Emissions of pollutant for each county by model rig well type category (tons/yr)

$Depth$ = Total depth drilled in model rig well type category by county (1,000 feet/yr)

EF_{poll} = Pollutant emission factor (tons/1,000 feet)

This process is repeated for each of the well category/engine type combinations of interest – for example, mechanical draw works engines used for shallow vertical wells (< 7,000 feet).

For 2006 onward, NO$_x$ emission estimates for the 110 counties in the eastern half of Texas subject to the Texas Low Emission Diesel (TxLED) program were adjusted downward by 6.2% to account for the effect of the rule. [6] Table 4-11 identifies the counties where this adjustment was made.

---

[6] The TxLED program requirements initiated in 2006, so these adjustments were not applied to the 2002 and 2005 modeling scenarios.

Table 4-11. TxLED Counties

Anderson	Denton	Johnson	Robertson
Angelina	Ellis	Karnes	Rockwall
Aransas	Falls	Kaufman	Rusk
Atascosa	Fannin	Lamar	Sabine
Austin	Fayette	Lavaca	San Jacinto
Bastrop	Franklin	Lee	San Patricio
Bee	Freestone	Leon	San Augustine
Bell	Fort Bend	Liberty	Shelby
Bexar	Galveston	Limestone	Smith
Bosque	Goliad	Live Oak	Somervell
Bowie	Gonzales	Madison	Tarrant
Brazoria	Grayson	Marion	Titus
Brazos	Gregg	Matagorda	Travis
Burleson	Grimes	McLennan	Trinity
Caldwell	Guadalupe	Milam	Tyler
Calhoun	Hardin	Montgomery	Upshur
Camp	Harris	Morris	Van Zandt
Cass	Harrison	Nacogdoches	Victoria
Chambers	Hays	Navarro	Walker
Cherokee	Henderson	Newton	Waller
Collin	Hill	Nueces	Washington
Colorado	Hood	Orange	Wharton
Comal	Hopkins	Panola	Williamson
Cooke	Houston	Parker	Wilson
Coryell	Hunt	Polk	Wise
Dallas	Jackson	Rains	
De Witt	Jasper	Red River	
Delta	Jefferson	Refugio	

For counties subject to TxLED requirements, NO_x emissions were estimated as follows:

$$\text{ENOx-type} = (\text{Depth } (1{,}000 \text{ feet/yr})) \times (\text{EFNOx } (\text{tons}/1{,}000 \text{ feet})) \times (0.938)$$

Where:

ENOx-type	=	Emissions of NOx for each county by model rig well type category (tons/yr)
Depth	=	Total depth drilled in model rig well type category by county (1,000 feet/yr)
EFNOx	=	NOx emission factor (tons/1,000 feet)
(0.938)	=	Adjustment Factor to account for 6.2% TxLED reduction

Total county level emissions were then determined by summing county level emissions for each of the three model rig categories for a given year.

4.3.1 Example Emission Calculations

Using the data above, CO emissions in 2008 for Anderson County from vertical wells > 7,000 feet are estimated as follows:

E_{CO} = (Depth (1,000 feet/yr)) x (EF_{poll} (tons/1,000 feet)), or
E_{CO} = (85 (1,000 feet/yr)) x (1.50E-01 (tons/1,000 feet))
E_{CO} = 12.7 (tons/yr)

As Anderson County is subject to the TxLED requirements, NO_x emissions in 2008 for Anderson County from vertical wells > 7,000 feet are estimated as follows:

E_{NO_x} = (Depth (1,000 feet/yr)) x (EF_{poll} (tons/1,000 feet)) x (0.938), or
E_{NO_x} = (85 (1,000 feet/yr)) x (4.15E-01 (tons/1,000 feet)) x (0.938)
E_{NO_x} = 33.1 (tons/yr)

4.4   Results

4.4.1 Emission Summary

Tables 4-12, through 4-15, as well as Figures 4-3 through 4-9 summarize the statewide annual and ozone-season daily criteria emissions totals for diesel engine drill rigs, for both controlled and uncontrolled scenarios. An Uncontrolled scenario was developed by combining year-specific activity levels with the 1990 emission rates generated using the NONROAD2008 model. The diesel engines operating in 1990 were not subject to emission controls and represent "uncontrolled" conditions. The Controlled scenario reflects the emission controls in place for any given year, and are accounted for in the NONROAD2008 model emission factors output for each analysis year. Depending upon the analysis year in question, one or more of the following emission controls are reflected in the Controlled scenario:

- Federal Emission Standards for Heavy-Duty and Non-Road Engines - "1998 HD and Non-Road Rule";
- Tier 1, 2 and Tier 3 Emission Standards: Control of Emissions of Air Pollution from Non-Road Diesel Engines - "Tier 1, 2 and 3 Rule"; and
- Clean Air Non-Road Diesel - Tier 4 Final Rule – "Tier 4 Rule", including ultra-low sulfur requirements for Non-Road diesel fuel.

In addition, the impact of the state TxLED rule is also included in all Controlled scenario estimates after 2005, as described above. None of these rules are accounted for in the Uncontrolled scenario.

HAP emissions estimates and by-county breakouts were provided in the electronic XML files submitted to the TCEQ under Task 2b of this study. Appendix A also provides the statewide emissions estimates for HAPs, while Appendix D provides county level breakouts for statewide annual and ozone season day emissions.

Figure 4-3. Statewide Drilling Rig Emissions – Controlled Scenario (NO$_x$ and CO Tons/Year)
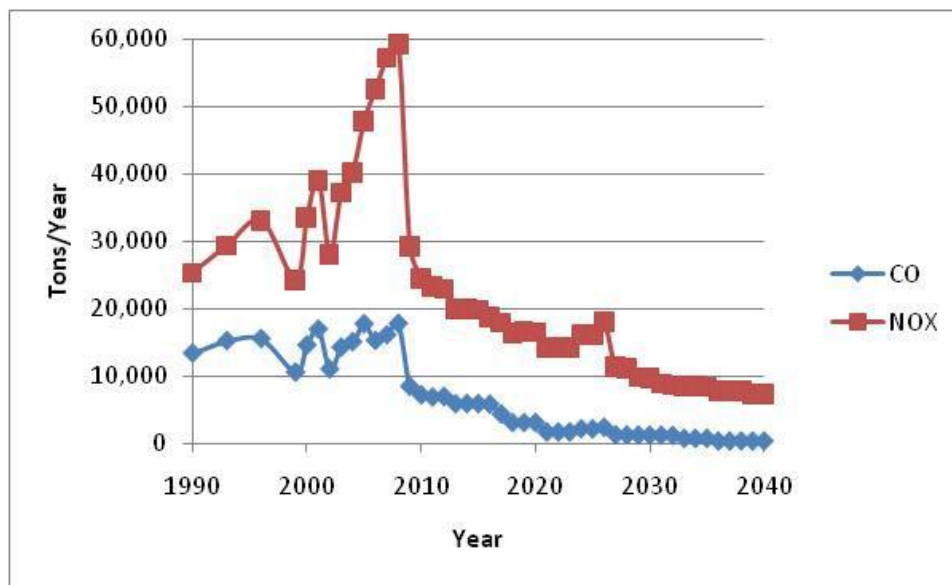

Figure 4-4. Statewide Drilling Rig Emissions – Controlled Scenario (VOC and SO₂ Tons/Year)
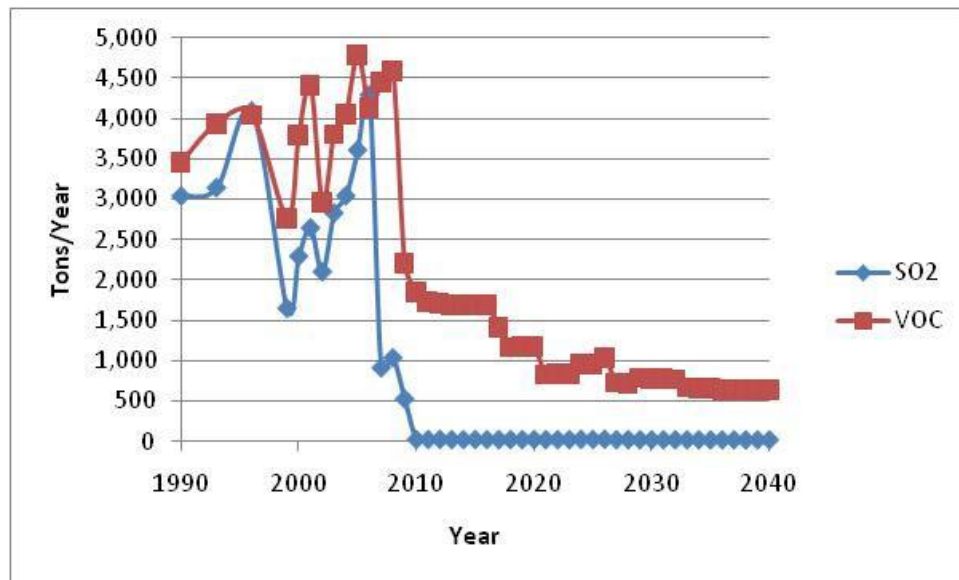

Figure 4-5. Statewide Drilling Rig Emissions – Controlled Scenario (PM₁₀ and PM₂.₅ Tons/Year)
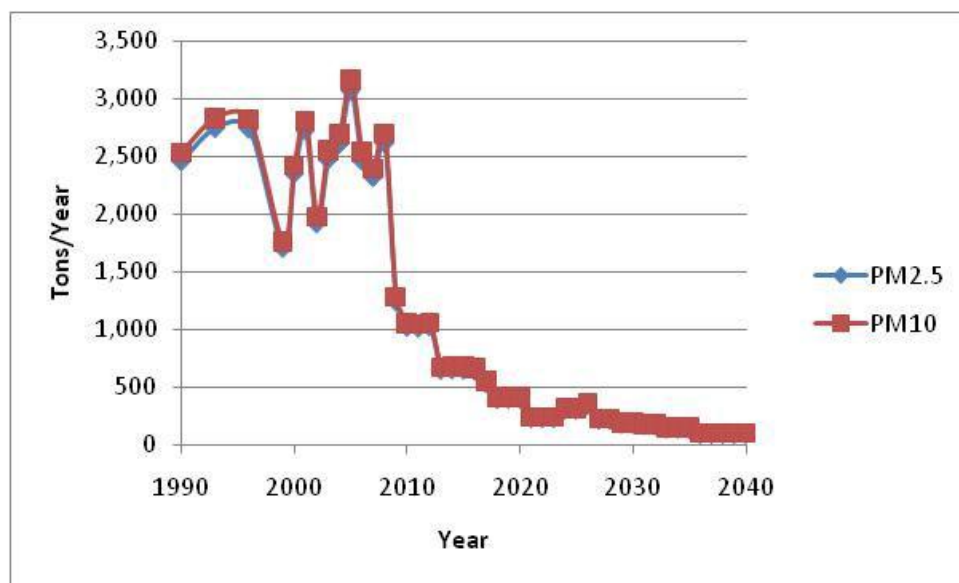

Figures 4.3 through 4.5 show a general increase in most pollutants between 1990 and 2008, after which time emissions drop off dramatically due to decreased drilling activity associated with the economic downturn and associated lower natural gas prices. Figure 4-6 presents the corresponding statewide drilling activity for comparison. CO emissions show the least variation over time, with the large emission rate improvement associated with the introduction of the Tier 2 emission standards (roughly 50% compared to prior

standards) in the early 2000's offsetting growth in drilling activity during this time. VOC and PM emissions trends are similar to CO, due to similar reductions associated with these same emission standards.

Figure 4-6. Statewide Annual Drilling Rig Activity (000's feet)
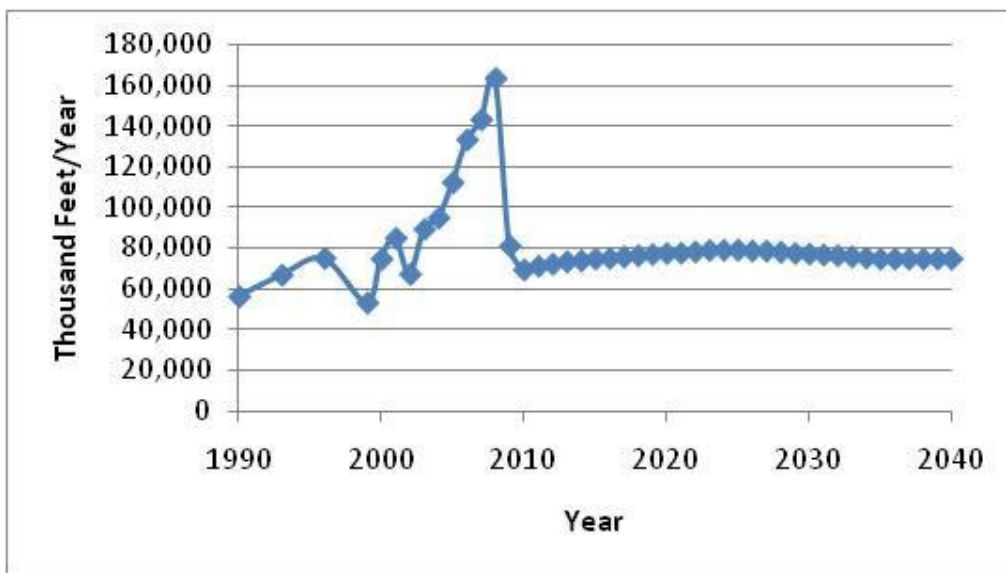

NO_x and SO_2 emissions trends display a somewhat different pattern during this time, however. NO_x emissions increase dramatically up through 2008, since the Tier 2 emission standards had a negligible impact on this pollutant, relative to the prior standard. (Substantial NO_x reductions are found with the introduction of the Tier 3 and 4 diesel emission standards, taking effect in the late 2000s and thereafter, however.)

SO_2 emissions are almost solely dependent on diesel fuel sulfur levels, and as long as these levels are constant over time, SO_2 emissions will track drilling activity in a one-to-one fashion. SO_2 emissions are seen to go negligible levels with the introduction of the Tier 4 ultra-low sulfur requirements after 2009. Other emission rates are projected to decrease more slowly as a result of continued penetration of cleaner Tier 3 and 4 engines, coupled with some decline in overall projected drilling activity.

Ozone season day (OSD) emissions were calculated by dividing annual emissions estimates by 365. These values are presented in the tables below. Note that trend charts are not presented for OSD totals, since the relative emissions over time do not change compared to the annual emissions cases above.

Table 4-13. Statewide OSD Emissions Totals (Tons/Day), Controlled Scenario

Figure 4-7. Statewide Drilling Rig Emissions – Uncontrolled Scenario (NO$_x$ and CO Tons/Year)
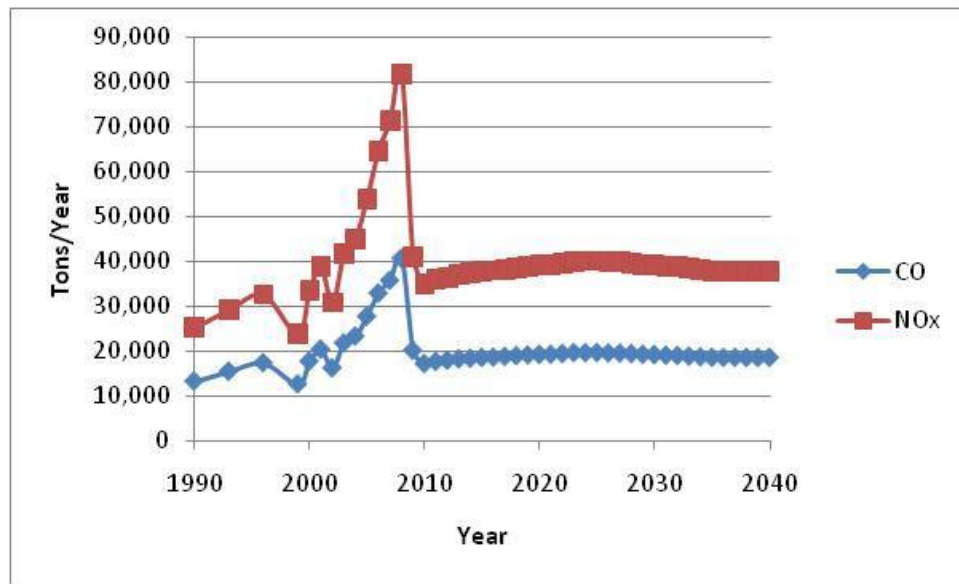

Figure 4-8. Statewide Drilling Rig Emissions – Uncontrolled Scenario (VOC and SO$_2$ Tons/Year)
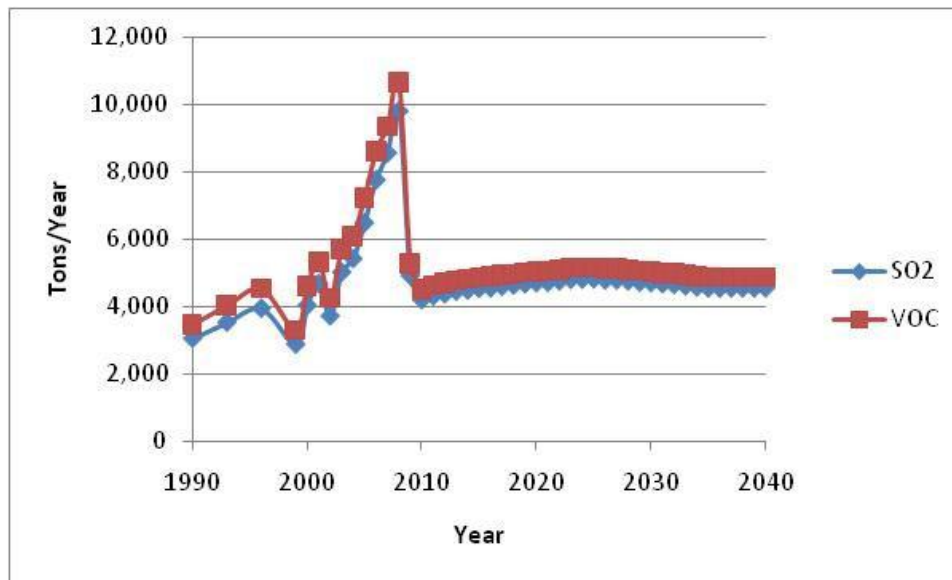

Figure 4-9. Statewide Drilling Rig Emissions – Uncontrolled Scenario (PM$_{10}$ and PM$_{2.5}$ Tons/Year)
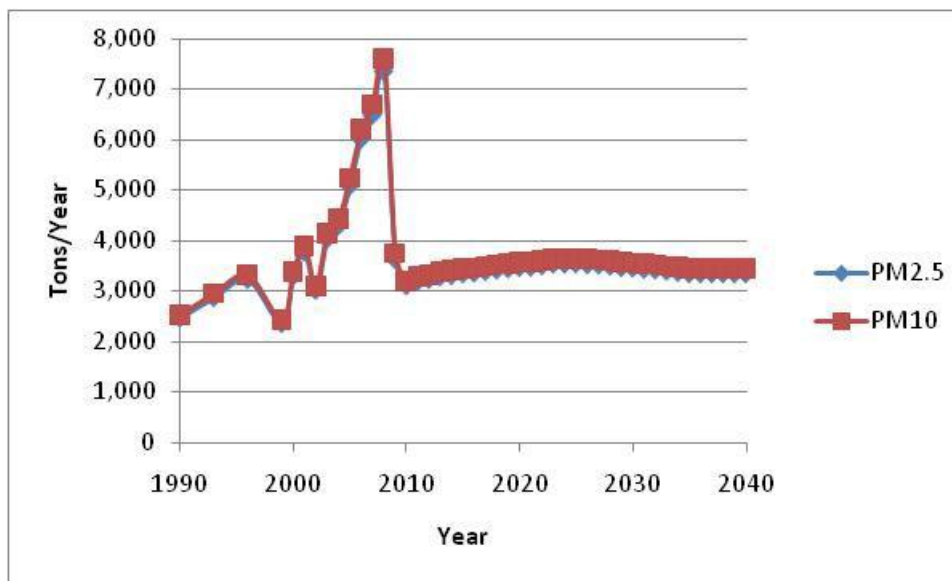

The emissions trends presented in Figures 4-7 through 4-9 above clearly show how emissions for all pollutants would be substantially higher without the benefit of the engine and fuel controls implemented since 1990. In addition, since emission rates are held constant for these estimates, the year-to-year changes shown above are exclusively due to changes in historical and projected drilling activity (see Figure 4-6).

Table 4-15. Statewide OSD Emissions Totals (Tons/Day), Uncontrolled Scenario

Year	NO$_x$	SO$_2$	VOC	CO	PM$_{10}$	PM$_{2.5}$

Annual county-level NO$_x$ emissions were also investigated for the Controlled scenario for the 2010 base year, in order to help identify the areas of the state with the greatest level of drill rig emissions. Table 4-16 presents these emissions, with counties ranked from highest to lowest. Of the 206 counties with non-zero emissions in 2010, only a small fraction were responsible for a preponderance of total statewide emissions. For example, the top 14 counties were responsible for 50 percent of total NO$_x$ emissions. In addition, 7 of the 14 counties were located in (largely rural) West Texas, with the others being Tarrant, Johnson, Wise, and Denton counties (North Central Texas), Freestone and Panola counties (East Texas), and Webb County (South Texas).

Table 4-16. County NO$_x$ Emissions Totals, Controlled Scenario (2010)

Trends in annual NO_x emissions were plotted for the top 10 counties for the entire analysis period, as shown below in Figure 4-10. While there is some relative variation in historical estimates, most county trends follow the general pattern seen in the statewide totals (see Figure 4-3).Figures 4-11, 4-12, and 4-13 display the county-level distribution of annual NO_x, VOC, and $PM_{2.5}$ emissions for the 2010 base year.

4.4.2 CERS XML Files

Once the emissions inventories were completed, CERS XML-formatted input files were prepared. For purposes of XML preparation, SCC 23-10-000-220 (Industrial Processes - Oil and Gas Exploration and Production - All Processes - Drill Rigs) was used, consistent with the 2009 study. ERG uploaded the CERS XML files to the TexAER test server to ensure the files were complete and accurate and in a format consistent with the TexAER area source file data requirements.

4.5 Quality Assurance

ERG conducted a variety of quality assurance checks consistent with the requirements of the Quality Assurance Project Plan (QAPP) submitted to the TCEQ for this effort. Key spreadsheet inputs and calculations used to estimate emissions were checked to ensure accuracy, and final emission estimates were evaluated for internal and external consistency, as described in detail in Drill Rig QA-QC_1.xlsx, submitted to the TCEQ as part of deliverable 2.2 of this effort. Errors identified during the QA were resolved and emissions estimates were subsequently revised prior to generation of the final XML files developed for TexAER.

The quality assurance tracking spreadsheet referred to above was broken into several components, each intended to evaluate different aspects of the study calculations. First, basic calculations were checked in ERG's working files, in order to identify potential errors in worksheet equations and data table inputs. Individual steps in the calculation QA process are listed separately, noting the goal of each QA check, how the check was performed, and the outcome of the check. If a check found an error, the correction result was also documented. A second set of QA checks were performed on the emissions inventory results themselves to help ensure consistency with expected results and the reasonableness of projection trends. Quantitative comparisons were made the with 2008 base year inventory results from the previous study, as well as more qualitative evaluations of emissions trends in relation to projected activity and the effectiveness the various engine and fuel controls being phased in over time. The following highlights some of the key findings from this analysis.

Key findings from the evaluation of final emission estimates include the following. First, the time series charts generated for the pollutants appear to follow a reasonable trend for future year projections, with significant activity and emissions drop offs occurring between 2008 and 2009. The differences in trends across pollutants appear to be explained by the differential impact of emission control phase-in schedules, as discussed in Section 4.4.1 above.

The results from the current study were also compared against the 2008 base year findings from the previous study, as summarized in Table 4-17.

Table 4-17. Comparison of Statewide 2008 Annual Emissions Totals (Tons/Year), Current and Previous Studies, Controlled Scenario

Year	Study	CO	NO$_x$	PM$_{10}$	PM$_{2.5}$	SO$_2$	VOC
2008	Previous	16,721	55,238	2,543	2,467	956	4,326
2008	Current	17,745	59,261	2,696	2,615	1,033	4,593
2008	% Diff	6.1%	7.3%	6.0%	6.0%	8.0%	6.2%

As seen in the table, the 2008 criteria pollutant emissions were found to be between 6 and 8 percent higher in current emission inventory than in 2009 study. The ERG staff responsible for processing the TRC data confirmed that an enhanced methodology was adopted for the current study to include additional drilling activity that was not included in the 2009 effort. This resulted in an increase of 8 percent in the statewide drill depth totals (163,348 v. 151,204). Since drill depth increases were not distributed uniformly across counties or well types (which have different emission factors), the resulting emission impact generally did not increase on a one-to-one basis with activity. However, as SO$_2$ emissions do in fact vary on a 1:1 basis with activity, independent of engine model year and emission standard, we see a precise match for this pollutant with activity (8 percent as expected).

Finally, trend graphs were generated to compare the difference between controlled and uncontrolled emissions scenarios (see Figures 4-14 through 4-18). As noted above, 1990 emission rates were used to represent the uncontrolled case for all scenario years. Controlled and uncontrolled emissions are shown in the following figures over the entire scenario year range.

Figure 4-14. Controlled and Uncontrolled Emissions Projections (NO$_x$ Tons/Year)
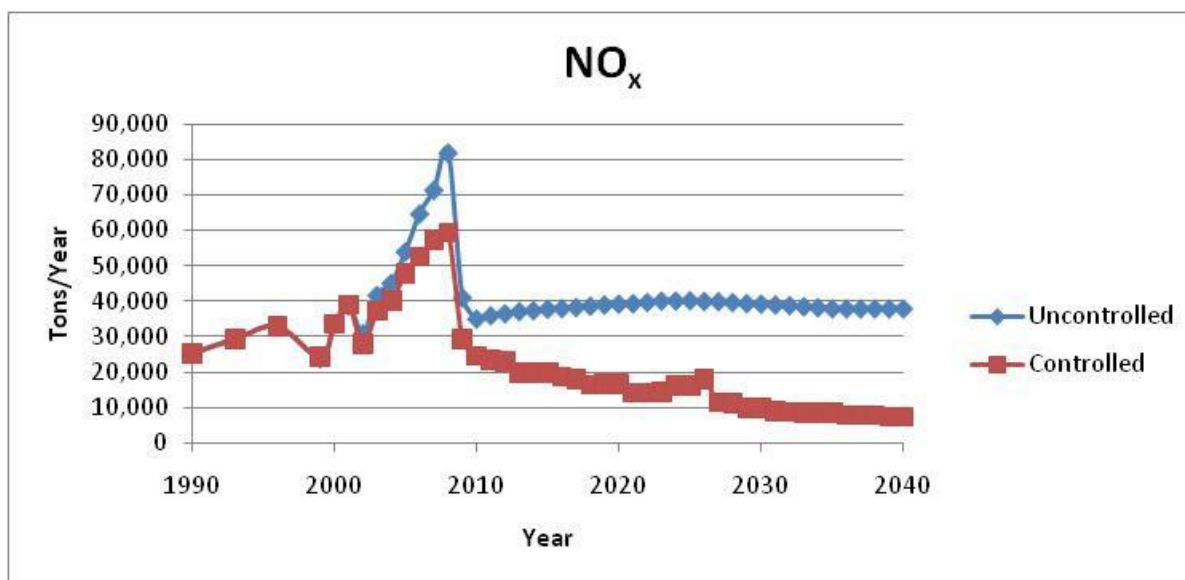

**Figure 4-15. Controlled and Uncontrolled Emissions Projections
(CO Tons/Year)**
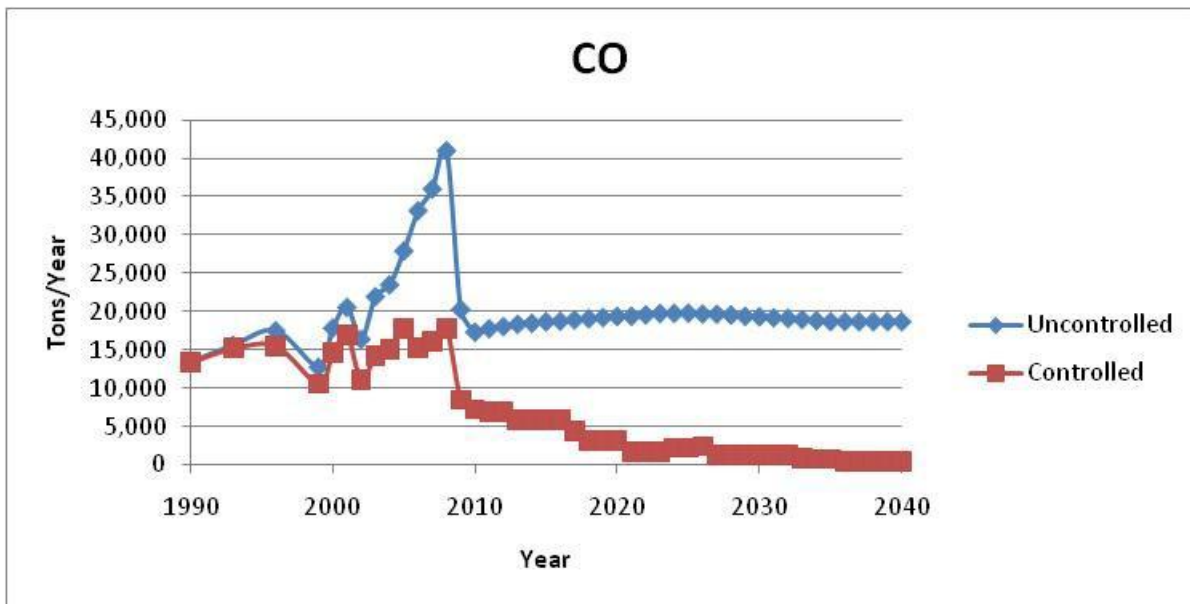

**Figure 4-16. Controlled and Uncontrolled Emissions Projections
(VOC Tons/Year)**
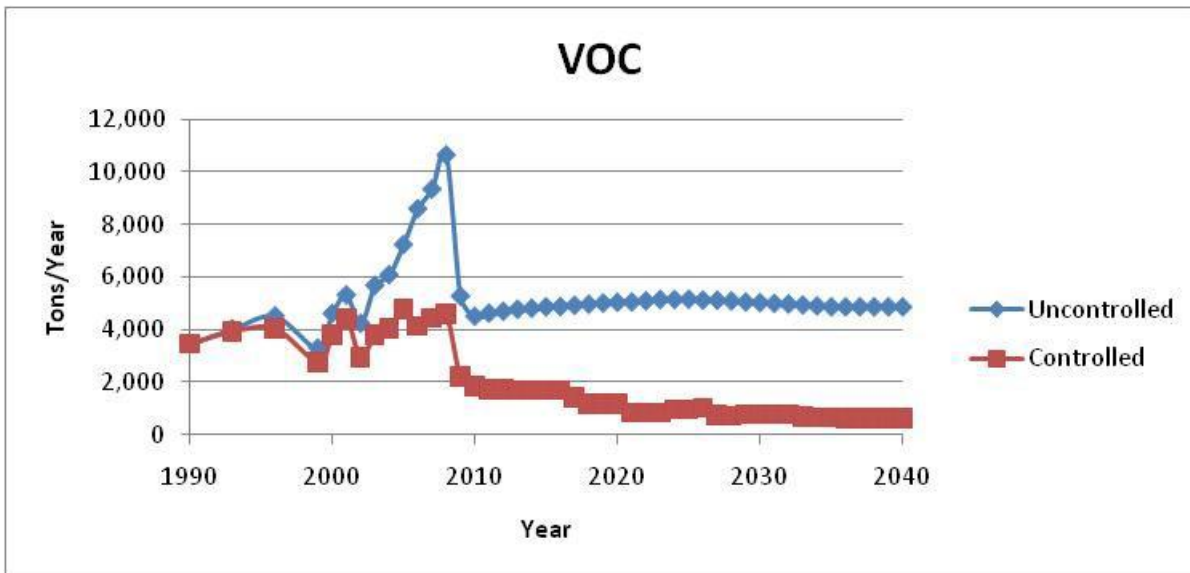

Figure 4-17. Controlled and Uncontrolled Emissions Projections (PM₁₀ Tons/Year)
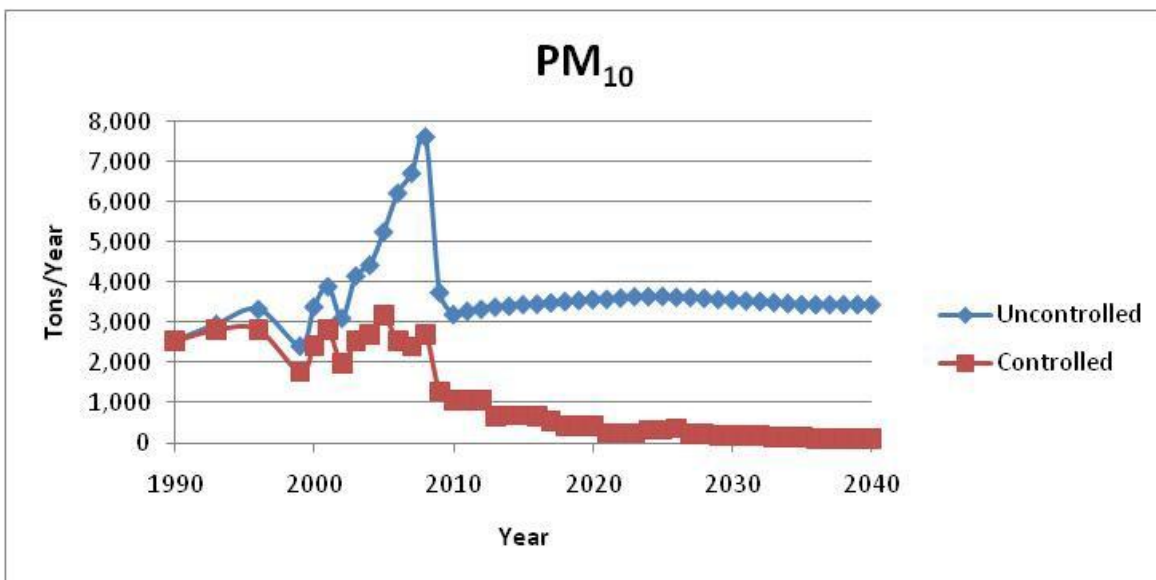

Figure 4-18. Controlled and Uncontrolled Emissions Projections (SO₂ Tons/Year)
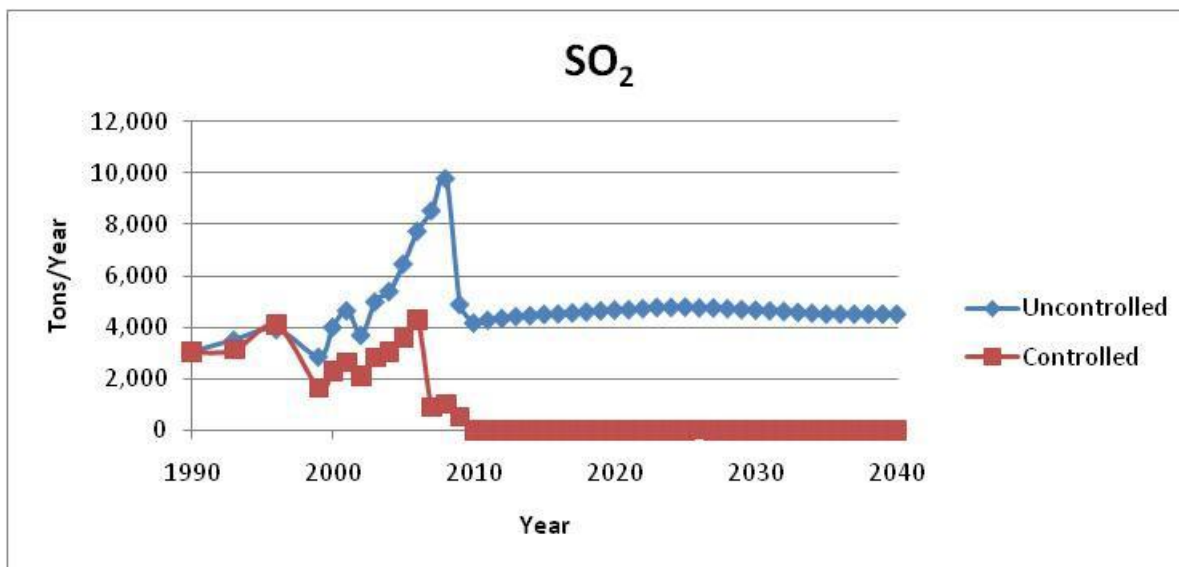

The difference between the controlled and uncontrolled emissions deviate more and more over time, as expected. The NO_x deviation shown above is not significant until substantial penetration of Tier 3+ emission standards in the late 2000's. The emissions benefit is more pronounced earlier for CO, VOC, and PM due to the greater benefit of the Tier 2 emission standards in the early 2000's, as discussed above in Section 4.4.1. SO_2 deviation shows the most abrupt increase (in 2010 when ultra-low diesel sulfur

regulations are enacted), since emissions for this pollutant depends on fuel sulfur changes alone, as opposed to fleet turnover.

5.   Conclusions and Recommendations

This study presents comprehensive, statewide emissions inventories for Texas for drilling rig engines. These inventories were prepared using well drilling activity data obtained through permit records from the TRC, combined with emissions data derived through detailed drilling rig engine data collected through a bottom-up survey effort conducted for the 2009 study. The study represents a significant improvement upon the 2009 effort, utilizing improved gap filling methods for the TRC dataset to obtain a more complete and accurate set of drill rig activity. In addition, this study utilized historical drilling data from the TRC to estimate past emissions, rather than relying on surrogate based back-casting from a base year, as was done in the previous study. Finally, the study greatly expanded the time horizon of the previous study, ranging from 1990 with projections through 2040. The result is a reliable, temporally resolved profile of county-level drilling activity emissions. The successful update of the TexAER system with this data, associated with a new area source SCC, will allow for improved SIP and trend analysis for all regions of the state.

Based on the projected oil and gas production levels in Texas from the EIA, drilling activity is estimated to remain relatively constant across the state from 2011 through 2035. However, the continued phase-in of more stringent Non-Road diesel engine emission standards should cause a steady decrease in drilling-related emissions over time. SO_2 emissions levels in particular are estimated to have fallen precipitously due to the introduction of the ultra-low sulfur standards for diesel fuel in 2010, and should remain extremely low for the foreseeable future.

An analysis of county-level data found that the vast majority of Texas counties produced some level of emissions associated with drilling activities (206 of 254 counties) in the 2010 base year. However, the county-level distribution of NO_x emissions is highly skewed, with 14 counties being responsible for 50 percent of total statewide NO_x in 2010. In addition, the preponderance of the high NO_x emitting counties were predominantly in West and North-Central Texas.

While the emissions inventory results provide an excellent basis for assessing historical emissions levels, significant sources of uncertainty remain. Most importantly, projections of future activity are highly uncertain, subject to significant rises and falls depending upon economic factors and associated oil and gas prices. Accordingly, periodic refinement of the activity data used for projected years 2011 through 2040 is strongly recommended to account for such factors. In addition, the contribution of fracturing operations to drilling activity emissions remains unknown at this time. Given that fracturing activities occur at the end of the completion phase, that the engines involved are brought in after the removal of the main drilling equipment, and that

fracturing may recur in the future at undetermined intervals to re-invigorate flows, fracturing emissions may merit a new SCC to facilitate future inventory development.
